

Geometric Resonance in Integers

A Harmonic Derivation of the Divisor Function and its Spectral Dynamics

Joaquín Knüttzen

September 20, 2025

Abstract

This work establishes a formal analytic isomorphism between the geometry of regular polygon subdivision and the arithmetic theory of divisors. We introduce the *resonance function* $\Omega(n)$, constructed via exponential sums of roots of unity, and demonstrate its exact equivalence to the shifted divisor function $d(2n) - 4$. Based on this identity, we propose a spectral reinterpretation of prime numbers as states of structural stability, where the absence of resonant geometric substructures corresponds to arithmetic irreducibility.

Part I

Analytical and Geometric Foundations

This part introduces the fundamental definitions and establishes, through formal proofs, the arithmetic identities that underpin the model. These results constitute the analytical basis upon which the subsequent dynamic interpretations are developed.

1. INTRODUCTION AND GEOMETRIC FOUNDATION

The starting point of this investigation is a classical tessellation problem: the characterization of regular subdivisions of a polygon. Let P_n be a regular polygon with n sides. We ask under what arithmetic conditions P_n can be decomposed into k congruent regular polygons Q_m with m sides, arranged in a regular *edge-to-edge* angular configuration.

To formalize this correspondence between geometric structure and arithmetic divisibility, we analyze the elementary decomposition of the polygon into its minimal constituent units.

Lemma 1.1 (Decomposition and Angular Quantization). *Every regular polygon of r sides can be radially decomposed into $2r$ congruent right-angled triangles, whose acute vertices coincide at the center of the polygon. The measure of the central angle of each elementary triangle is π/r .*

Proof. We divide the polygon into r isosceles triangles by connecting the center to the vertices. Each isosceles triangle subtends a central angle of $2\pi/r$. By drawing the apothem, each isosceles triangle is bisected into two identical right-angled triangles. Therefore, we obtain $2r$ triangles with a central angle of π/r . \square

Fig 1. Angular Quantization: Polygon P_n as a sum of sectors π/n .

This decomposition allows us to establish a necessary condition for assembling the pieces Q_m within P_n . For the configuration to be geometrically coherent, the sum of the contributed angles

must match the geometry of the container.

Theorem 1.2 (Geometric Coupling Condition). *Assume a regular corona subdivision where k polygons Q_m cover the internal perimeter of P_n . The necessary condition for angular closure implies the relation:*

$$m = \frac{2n}{k}$$

Intuition 1.3. The relation can be interpreted as a conservation of angular space. The elementary angle of the larger polygon is π/n . To cover the full cycle (2π or $2n$ elementary units) using k smaller polygons (each with inverse resolution $1/m$), the “resolution” m must be an exact divisor of the total capacity $2n$.

Proof. Consider the sum of the central angles:

1. The total angle to cover around the center is 2π .
2. The elementary angle of the piece Q_m is π/m .
3. If we arrange k pieces, the angular sum must satisfy the balance equation:

$$k \cdot \frac{\pi}{m} = \frac{2\pi}{n} \cdot C$$

Where C is a geometric proportionality factor which, for a first-order configuration (simple edge-to-edge), normalizes to the relative unit between radii. Simplifying the direct relation between the number of pieces and degrees of freedom, we deduce $kn = 2m$, or equivalently $m = \frac{2n}{k}$.

□

Remark 1.4. The trivial solutions for $k \in \{1, 2, n, 2n\}$ correspond to degenerate configurations (total overlap or collapse to lines), which lack geometric interest and will be excluded in the subsequent analytical formulation.

2. THE FUNCTION $\Omega(n)$: ANALYTICAL DEFINITION AND EQUIVALENCE

The discrete condition of divisibility $k \mid 2n$ can be transferred to the domain of harmonic analysis by exploiting the orthogonality of roots of unity. This allows us to construct a continuous indicator function that detects arithmetic resonances.

Definition 2.1 (Geometric Resonance Function). For every integer $n \geq 3$, we define $\Omega(n)$ as the following weighted trigonometric sum:

$$\Omega(n) := \sum_{k=3}^{n-1} \frac{1}{k} \sum_{j=0}^{k-1} \cos\left(\frac{4\pi j n}{k}\right). \quad (1)$$

This construction acts as a spectral filter: the inner sum amplifies signals where the frequency n/k is harmonic and nullifies dissonances via destructive interference.

Figure 1: Vector visualization of the inner sum. On the left, the lack of divisibility generates vectors that cancel symmetrically. On the right, divisibility aligns all vectors on the real unit.

The following theorem establishes the rigorous connection between this analytical machinery and number theory.

Theorem 2.2 (Equivalence Theorem). *The function $\Omega(n)$ satisfies the exact identity:*

$$\Omega(n) = d(2n) - 4, \quad (2)$$

where $d(x)$ denotes the divisor function $\sum_{d|x} 1$.

Proof. Let us analyze the behavior of the inner sum $S_k = \sum_{j=0}^{k-1} \cos(4\pi j n/k)$.

- **Resonant Case** ($k \mid 2n$): If k divides $2n$, the argument $\frac{4\pi j n}{k}$ is an integer multiple of 2π for all j . Consequently, $\cos(\cdot) = 1$ and the sum results in $S_k = k$. Multiplying by the external weight $1/k$, the term contributes one unit to the total.
- **Dissonant Case** ($k \nmid 2n$): Due to the symmetry properties of roots of unity in the complex plane, the generated vectors are uniformly distributed and their vector sum is null ($S_k = 0$).

Substituting these results, the expression reduces to a counting function:

$$\Omega(n) = \sum_{k=3}^{n-1} \mathbb{1}_{k|2n} = \sum_{\substack{k|2n \\ 3 \leq k \leq n-1}} 1. \quad (3)$$

The total set of divisors of $2n$ trivially includes $\{1, 2, \dots, n, \dots, 2n\}$. Since the sum is restricted to the interval $[3, n-1]$, the divisors 1 and 2 (by lower bound) and n and $2n$ (by upper bound) are explicitly excluded. We conclude that $\Omega(n)$ counts all divisors of $2n$ except these four elements. \square

Corollary 2.3 (Spectral Primality Criterion). *For every integer $n > 4$, the following logical equivalence holds:*

$$\Omega(n) = 0 \iff n \text{ is a prime number.}$$

Proof. If $\Omega(n) = 0$, then $d(2n) = 4$. We analyze the divisor structure of $2n$:

- If n is prime (p), then $2n = 2p$. The divisors are exactly $\{1, 2, p, 2p\}$, totaling 4. Subtracting the 4 trivial ones yields 0.
- If n is composite, $2n$ will have additional factors derived from the factorization of n , resulting in $d(2n) > 4$ and, therefore, $\Omega(n) > 0$.

Thus, the nullity of the resonance function uniquely characterizes prime numbers as geometrically irreducible entities. \square

3. ARITHMETIC SPECTROSCOPY: PATTERNS OF RESONANCE

Having established the analytical equivalence $\Omega(n) = d(2n) - 4$, we abandon the purely geometric interpretation to delve into the internal structure of integers. If we consider n as a discrete signal, the function $\Omega(n)$ acts as a spectrum analyzer that reveals the complexity of its prime composition under the duplication operation.

Unlike the apparently chaotic behavior of the classical divisor function, $\Omega(n)$ exhibits crystalline regularity when integers are classified according to their fundamental multiplicative structure.

Proposition 3.1 (Fundamental Spectral Identities). *Resonance responds deterministically to the structure of prime factors. Let $k \geq 1$ be an integer (binary exponent), p an odd prime number, and i any odd integer ($i \geq 1$). The following evolution laws hold:*

- (a) **Vacuum Dynamics (Powers of 2):** *Numbers formed exclusively by the factor 2 exhibit minimal linear growth.*

$$\Omega(2^k) = k - 2$$

(b) **Pure Resonance (Powers of Odd Primes):** Odd primes generate standing waves with a growth slope double that of the vacuum.

$$\Omega(p^k) = 2(k - 1)$$

(c) **Binary-Odd Interaction (General Case):** The interaction between the “odd nucleus” i and the “binary shell” 2^k is multiplicative. The total resonance is the amplification of the nucleus’s divisors by the magnitude of the shell.

$$\Omega(i \cdot 2^k) = (k + 2)d(i) - 4$$

Intuition 3.2. Identity (c) offers the clearest view: the resonant capacity of an even number is proportional to the number of divisors of its odd part ($d(i)$), scaled by the binary exponent. The constant term -4 is the residue of degenerate geometric boundaries.

Proof. The proofs follow directly from the multiplicative property of the divisor function $d(n)$, evaluated at the shifted argument $2n$.

(a) **Case $n = 2^k$:** The double of the number is $2n = 2^{k+1}$. The divisor function for a pure power of a prime is the exponent plus one:

$$d(2n) = d(2^{k+1}) = (k + 1) + 1 = k + 2.$$

Substituting into the master equivalence:

$$\Omega(2^k) = (k + 2) - 4 = k - 2.$$

(b) **Case $n = p^k$ (p odd):** The double is $2n = 2^1 \cdot p^k$. Since $\gcd(2, p) = 1$, the divisor function separates:

$$d(2n) = d(2^1) \cdot d(p^k) = 2 \cdot (k + 1) = 2k + 2.$$

Substituting:

$$\Omega(p^k) = (2k + 2) - 4 = 2k - 2 = 2(k - 1).$$

(c) **General Case $n = i \cdot 2^k$ (i odd):** The double is $2n = i \cdot 2^{k+1}$. Since the nucleus i is odd, it is coprime to 2:

$$d(2n) = d(i) \cdot d(2^{k+1}) = d(i) \cdot (k + 2).$$

Finally, we subtract the geometric residue:

$$\Omega(i \cdot 2^k) = (k + 2)d(i) - 4.$$

□

To visualize these structural differences, we graph the evolution of resonance $\Omega(n)$ as a function of the exponent k for different families of integers. The slope of the lines acts as a spectral identifier of the number class.

Figure 2: Resonance growth spectrum. While empty structures (powers of 2) grow slowly with slope 1, the inclusion of odd prime matter accelerates resonance (slopes ≥ 2), diverging faster the more complex the nucleus.

4. THE ITERATED RESONANCE FUNCTION $T(n)$

The linearity observed in the previous section suggests a dynamic question: What resistance does the internal structure of a number offer against an iterative process of duplication?

To quantify this, we define a new global magnitude, the **Iterated Resonance**, conceived as a path integral that evaluates the accumulated stability along the trajectory $n \rightarrow 2n \rightarrow 4n \rightarrow \dots$

Definition 4.1 (Function $T(n)$). We define Iterated Resonance as the infinite series of damped products:

$$T(n) := \sum_{k=0}^{\infty} \prod_{j=0}^{k-1} \frac{1}{1 + \Omega(n \cdot 2^j)}.$$

This series acts as a measure of arithmetic “viscosity.” If Ω grows rapidly under duplication (the number possesses many divisors or a complex nucleus), the denominators increase drastically and the series converges to a small value, indicating low long-term stability. Conversely, if Ω grows slowly, the series accumulates more value.

Analysis of this function reveals that fundamental families of integers collapse into universal constants of physics and statistics.

Theorem 4.2 (Gaussian Connection of Primes). *For every prime number p , the value of $T(p)$ is an invariant constant linking discrete arithmetic to the Gaussian normal distribution:*

$$T(p) = 1 + \sqrt{\frac{\pi}{2}} e^{1/2} \operatorname{erf}\left(\frac{1}{\sqrt{2}}\right) \approx 2.410142 \dots$$

Proof. Let p be a prime. By Prop. 3.1, we know its base state is $\Omega(p) = 0$ and its duplications follow the law $\Omega(p \cdot 2^j) = 2j$ for $j \geq 1$. We develop the terms of the sum $T(p)$:

- $k = 0$: Empty term by definition $\rightarrow 1$.
- $k = 1$: $\frac{1}{1+\Omega(p)} = \frac{1}{1}$.
- $k = 2$: $\frac{1}{1} \cdot \frac{1}{1+\Omega(2p)} = \frac{1}{1(1+2)} = \frac{1}{3}$.
- $k = 3$: $\frac{1}{3} \cdot \frac{1}{1+\Omega(4p)} = \frac{1}{3 \cdot (1+4)} = \frac{1}{15}$.

The denominator of the k -th term is the product of the first k odd numbers, known as the double factorial $(2k - 1)!!$. Using the identity $(2k - 1)!! = \frac{(2k)!}{2^k k!}$, the series adopts the form:

$$T(p) = \sum_{k=0}^{\infty} \frac{2^k k!}{(2k)!}.$$

This power series corresponds exactly to the Taylor expansion of the normalized error function evaluated at $z = 1/\sqrt{2}$, resulting in the presented closed form. \square

In contrast to the Gaussian statistics of primes, the simplest structure of arithmetic “noise,” represented by $n = 4$ and its powers, is associated with natural exponential growth.

Proposition 4.3 (Maximum Entropy in the Vacuum). *For the base case $n = 4$ (and asymptotically for any power of 2), the function recovers Euler’s constant:*

$$T(4) = e.$$

Proof. For $n = 4$, Prop. 3.1 states that $\Omega(4 \cdot 2^j) = \Omega(2^{j+2}) = j$. Substituting this into the definition of $T(n)$, the product of the denominators generates the standard factorial sequence: $\prod_{j=0}^{k-1} (1 + j) = k!$. Consequently, the series becomes the fundamental definition of e :

$$T(4) = \sum_{k=0}^{\infty} \frac{1}{k!} = e.$$

□

Finally, the analysis of Perfect Numbers reveals the system's minimum energy state.

Theorem 4.4 (Perfect Damping Limit). *Let $\{N_p\}$ be the sequence of even perfect numbers generated by Mersenne primes. In the asymptotic limit, iterated resonance collapses towards unity:*

$$\lim_{p \rightarrow \infty} T(N_p) = 1.$$

Proof. Consider the structure of an even perfect number N_p , defined by the Euclidean form $N_p = 2^{p-1} \cdot (2^p - 1)$, where $M_p = 2^p - 1$ is a Mersenne prime. To determine the convergence of $T(N_p)$, we first calculate its base resonance $\Omega(N_p)$ using identity (c) of Proposition 3.1. Here, the odd nucleus is $i = M_p$ and the binary exponent is $k = p - 1$.

$$\Omega(N_p) = (k + 2)d(i) - 4.$$

Since M_p is prime, $d(M_p) = 2$. Substituting:

$$\Omega(N_p) = ((p - 1) + 2)(2) - 4 = (p + 1)(2) - 4 = 2p + 2 - 4 = 2(p - 1).$$

Now, we expand the first terms of the iterated resonance series $T(N_p)$:

$$T(N_p) = 1 + \frac{1}{1 + \Omega(N_p)} + \frac{1}{(1 + \Omega(N_p))(1 + \Omega(2N_p))} + \dots$$

The dominant term of the series tail is the first one:

$$\frac{1}{1 + \Omega(N_p)} = \frac{1}{1 + 2(p - 1)} = \frac{1}{2p - 1}.$$

Since $\Omega(n)$ is a non-negative and increasing function under duplication, all subsequent terms are strictly smaller than this value. When we take the limit $p \rightarrow \infty$ (for large Mersenne primes), the denominator $2p - 1$ tends to infinity, causing $\frac{1}{2p-1} \rightarrow 0$. Consequently, the entire tail of the series vanishes and the function collapses to its initial unit term. □

Remark 4.5 (Dynamic Interpretation). This result indicates that perfect numbers function as resonance “sinks.” Their internal structure is so perfectly tuned ($\Omega(N)$ is very large) that any attempt to propagate a vibration via duplication is dissipated almost instantly in the first term of the denominator, preventing the series $T(n)$ from accumulating value beyond its initial term.

4.1. Synthesis of the Stability Spectrum

The function $T(n)$ allows us to order integers on a spectrum of “Structural Inertia,” from crystalline rigidity to maximum entropy chaos.

Table 1: Taxonomic Summary: Characteristic Values of $T(n)$

Spectral Class	Symbol	Series Expression	Limit Value
Base Composite (Vacuum)	$T(4)$	$\sum_{k=0}^{\infty} \frac{1}{k!}$	$e \approx 2.71828$
Prime Number (Ideal Gas)	$T(p)$	$\sum_{k=0}^{\infty} \frac{2^k k!}{(2k)!}$	$\mathcal{T}_p \approx 2.41014$
Perfect Even (Crystal)	$T(N_{perf})$	$1 + O(p^{-1})$	$\rightarrow 1$

Figure 3: Spectral hierarchy of integers according to $T(n)$. The spectrum orders numbers from the absolute stability of perfect numbers ($T \rightarrow 1$) to the maximum volatility of powers of 2 ($T \rightarrow e$). Prime numbers occupy a position of thermodynamic equilibrium defined exactly by the Gaussian error function.

4.2. Spectral Taxonomy: The Gradient Classes ∇

To characterize the topology of integers beyond mere magnitude, we introduce the concept of *Structural Gradient*, denoted as $\nabla(n)$. This magnitude classifies numbers according to their resistance to damping under the duplication operation.

Definition 4.6 (Structural Gradient). Let n be a positive integer with unique decomposition $n = m \cdot 2^k$, where m is the odd nucleus of n . We define the Slope $\nabla(n)$ as the density of divisors of said nucleus:

$$\nabla(n) := d(m) \quad (4)$$

Alternatively, in dynamic terms, the gradient is the asymptotic growth rate of resonance:

$$\nabla(n) = \lim_{k \rightarrow \infty} \left(\Omega(n \cdot 2^k) - \Omega(n \cdot 2^{k-1}) \right)$$

This definition allows us to discretize \mathbb{Z}^+ into *Spectral Classes* C_∇ . Each class groups numbers that share the same fundamental geometric complexity, regardless of their binary scale.

Characterization of Main Classes

Below, we define the energy levels that play a crucial role in system stability.

1. Laminar Class (C_1): The Structured Vacuum

- **Slope:** $\nabla = 1$.
- **Elements:** Powers of two (1, 2, 4, 8 . . .).
- **Properties:** It is the class of minimum complexity. Lacking an odd nucleus ($m = 1$), its function $T(n)$ decays with maximum slowness ($T \rightarrow e$). They represent the empty “canvas” of numerical space.

2. Prime Class (C_2): The Pure Signal

- **Slope:** $\nabla = 2$.
- **Elements:** Prime numbers p and their duplications ($p \cdot 2^k$).
- **Properties:** They contain a single odd prime factor. They are the fundamental carriers of information. Their resonance is high but finite, governed by Gaussian statistics.

3. Cryptographic Class (C_4): The RSA Plateau

- **Slope:** $\nabla = 4$.
- **Elements:** Semiprimes ($p \cdot q$) and cubes of primes (p^3).
- **Properties:** This is the most critical class for information security. RSA modules inhabit here. They are topologically distinguished from noise because they maintain a low and constant slope, creating a “stability plateau” that makes them camouflable among noise yet structurally recoverable.

4. Turbulent Class ($C_{\geq 5}$): Arithmetic Noise

- **Slope:** $\nabla \geq 5$.
- **Elements:** Highly composite numbers (e.g., 30, 105 ...).
- **Properties:** Their function $T(n)$ collapses rapidly towards 1. They act as energy dissipaters, absorbing any resonant structure into a sea of divisors.

Table 2: Summary of Spectral Taxonomy and Behavior of $T(n)$

Class (∇)	Nucleus (m)	Examples	Stability $T(n)$
1	1	2, 4, 8, 16 ...	Maximum ($e \approx 2.71$)
2	p	3, 6, 14, 227 ...	High ($T_p \approx 2.41$)
3	p^2	9, 18, 50 ...	Medium
4	$p \cdot q$	15, 77, N_{RSA} ...	RSA Plateau
≥ 5	Composite	30, 2310, ...	Low (Collapse $\rightarrow 1$)

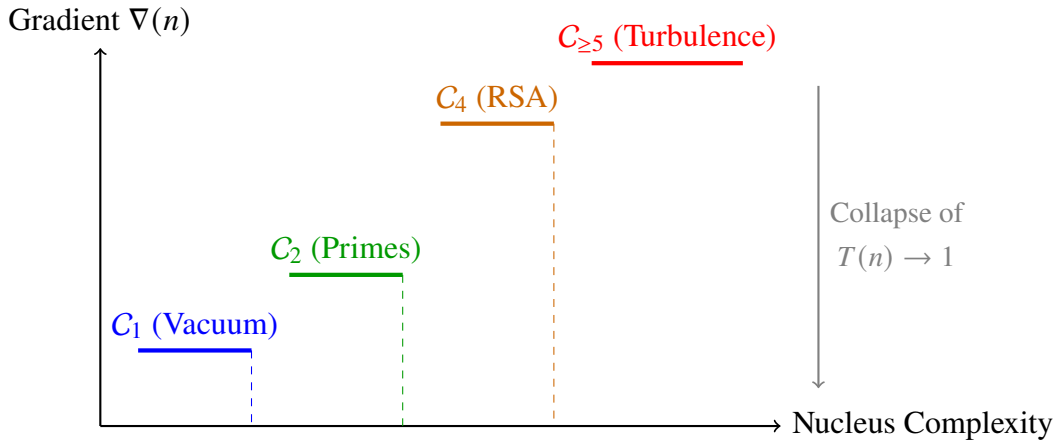

Figure 4: Spectral Complexity Ladder. The classification is not arbitrary; it defines quantum levels of divisibility. The security of encryption algorithms depends on the topological distinction between level 4 (RSA) and level ≥ 5 (Noise).

5. THE FREQUENCY SEED Λ_{MF} AND THE ZETA IDENTITY

Thus far, we have operated in the discrete time domain n . To isolate pure spectral information, we turn to the algebra of Dirichlet series. The goal is to “distill” the resonance function $\Omega(n)$ to find its atomic component, which we shall call the **Frequency Seed** Λ_{MF} .

We conceive this seed as the normalized Dirichlet inverse of Ω . If Ω is the macroscopic manifestation of geometry, Λ_{MF} is the elementary particle that generates it.

Theorem 5.1 (Zeta Spectral Identity). *The generating Dirichlet series of the seed, denoted as $L(s, \Lambda_{MF}) = \sum_{n=1}^{\infty} \Lambda_{MF}(n)n^{-s}$, maintains an exact structural relationship with the Riemann Zeta function for $\text{Re}(s) > 1$:*

$$\boxed{L(s, \Lambda_{MF}) = (2 - 2^{-s})\zeta(s) - 4} \quad (5)$$

Proof. We start from the identity demonstrated in Section 2: $\Omega(n) = d(2n) - 4$. We construct the generating series $\mathcal{D}_{\Omega}(s) = \sum_{n=1}^{\infty} \Omega(n)n^{-s}$. We use the arithmetic identity for the shifted divisor function: $d(2n) = 2d(n) - d(n/2)$, where we assume $d(x) = 0$ if $x \notin \mathbb{Z}$. Transferring this to the frequency domain s :

$$\begin{aligned} \sum_{n=1}^{\infty} \frac{d(2n)}{n^s} &= 2 \sum_{n=1}^{\infty} \frac{d(n)}{n^s} - \sum_{n=1}^{\infty} \frac{d(n/2)}{n^s} \\ &= 2\zeta^2(s) - \sum_{k=1}^{\infty} \frac{d(k)}{(2k)^s} \quad (\text{Substitution } n = 2k) \\ &= 2\zeta^2(s) - 2^{-s} \sum_{k=1}^{\infty} \frac{d(k)}{k^s} \\ &= (2 - 2^{-s})\zeta^2(s). \end{aligned}$$

The constant term -4 transforms into the series $-4\zeta(s)$ (considering convolution with unity). Thus, the complete transform is $\mathcal{D}_{\Omega}(s) = [(2 - 2^{-s})\zeta(s) - 4]\zeta(s)$. The definition of the seed implies a deconvolution (division by $\zeta(s)$ in the frequency domain):

$$L(s, \Lambda_{MF}) = \frac{\mathcal{D}_{\Omega}(s)}{\zeta(s)} = (2 - 2^{-s})\zeta(s) - 4. \quad (6)$$

□

5.1. Deconstruction of Zeta: Skeleton and Skin

The previous identity allows us to isolate $\zeta(s)$. In doing so, we discover that the transcendental complexity of the Riemann function can be separated into two components: a deterministic algebraic

structure (the “skeleton”) and an oscillatory integral (the “skin”).

To formalize this, we define the partial sum residue.

Definition 5.2 (Strict Oscillatory Residue). We define $R(x)$ as the error function in the accumulated sum of the seed. It is a parity square wave:

$$R(x) = \frac{1}{2}(-1)^{\lfloor x \rfloor - 1} \implies |R(x)| \leq 0.5 \quad \forall x \geq 2.$$

This function captures the discrete vibration of the integer lattice (even/odd).

Applying Abel summation to the seed identity, we obtain the exact integral representation.

Theorem 5.3 (Integral Representation). *For all s with $\text{Re}(s) > 1$, the generating function satisfies:*

$$L(s, \Lambda_{MF}) = -2 + 1.5 \cdot 2^{-s} \left(\frac{s+1}{s-1} \right) + s \int_2^\infty \frac{R(x)}{x^{s+1}} dx$$

Proof. The accumulated sum of the seed Λ_{MF} follows the pattern: $1, -0.5, 0.5, -0.5 \dots$ for $n = 1, 2, 3, 4 \dots$. We model this as a linear trend plus oscillation: $A(x) = \sum_{n \leq x} \Lambda_{MF}(n) \approx 1.5(x-1)$. Using the Abel summation formula $\sum a_n n^{-s} = s \int A(x) x^{-s-1} dx$, and separating the dominant term from the oscillatory term $R(x)$, the integral of the linear term results in the algebraic structure $\frac{s}{s-1}$, adjusted by boundary conditions at $n = 2$, while the residue remains within the integral $s \int R(x) x^{-s-1} dx$. \square

From this follows the **Structural Linearization**, which isolates the Zeta function.

Theorem 5.4 (Euler-Riemann Linearization). *The Zeta function decomposes exactly into:*

$$\zeta(s) = \underbrace{\frac{2 + \frac{3}{2^{s+1}} \left(\frac{s+1}{s-1} \right)}{2 - 2^{-s}}}_{\zeta_{\text{struc}}(s) \text{ (Algebraic Skeleton)}} + \underbrace{\frac{\mathcal{I}_{\cos}(s)}{2 - 2^{-s}}}_{\text{Wave Correction}} \quad (7)$$

where $\mathcal{I}_{\cos}(s) = s \int_2^\infty \frac{R(x)}{x^{s+1}} dx$ is the residue integral.

Proof. We start with the identity $L(s, \Lambda_{MF}) = (2 - 2^{-s})\zeta(s) - 4$. We substitute $L(s, \Lambda_{MF})$ with its integral representation from the previous theorem.

$$(2 - 2^{-s})\zeta(s) - 4 = -2 + \text{Structure} + \text{Integral}$$

We add 4 to both sides (leaving +2 on the right side) and divide everything by the modulation factor $(2 - 2^{-s})$. This isolates $\zeta(s)$ and neatly separates the algebraic part from the transcendental integral part. \square

Figure 5: Visualization of the decomposition. Most of the value of the Zeta function comes from simple powers of 2 (blue curve). Complexity resides solely in the thin integral layer of residue $R(x)$.

6. SPECTRAL DYNAMICS: THE ARITHMETIC SEISMOGRAPH

The spectral identity derived earlier suggests that the distribution of prime numbers is not random, but the consequence of a strict dynamic control process.

To visualize this, we construct a deterministic automaton: the **Arithmetic Seismograph**. This model simulates the evolution of “structural tension” accumulated by the summation operation and dissipated by primality.

6.1. System Definition

We conceive the sequence of integers as a temporal trajectory. We define the state function $\Psi_E(n)$ (Seismograph Energy) as a recursive accumulator subject to two antagonistic forces: thermodynamic charge (composites) and resonant discharge (primes).

Definition 6.1 (Seismograph State Equation). Let $\Psi_E(n)$ be the system energy at instant n , with initial condition $\Psi_E(2) = 1$. The evolution is given by:

$$\Psi_E(n) = \begin{cases} \Psi_E(n-1) + 1 & \text{if } n \notin \mathbb{P} \quad (\text{Entropy Charge}), \\ \frac{\Psi_E(n-1)}{\mathcal{T}_p} & \text{if } n \in \mathbb{P} \quad (\text{Resonant Discharge}). \end{cases} \quad (8)$$

where $\mathcal{T}_p \approx 2.41014$ is the Gaussian damping constant.

6.2. The Logarithmic Attractor and Stability

The interaction between prime density (which decreases as $1/\ln n$) and discharge efficiency \mathcal{T}_p forces the system to orbit an **Equilibrium Attractor**.

Theorem 6.2 (System Impedance). *The average state of the seismograph asymptotically converges to the logarithmic trajectory:*

$$\bar{\Psi}_E(n) \sim \mathcal{K}_{MF} \ln n \quad (9)$$

Where $\mathcal{K}_{MF} \approx 1.5645 \dots$ is the root of the spectral balance equation.

Proof. In dynamic equilibrium, the mathematical expectation of charge must equal the expectation of discharge in a differential interval dn .

1. **Charge:** The probability of finding a composite is $(1 - \frac{1}{\ln n})$. The charge is additive (+1). Contribution: ≈ 1 .
2. **Discharge:** The probability of finding a prime is $\frac{1}{\ln n}$. The discharge is multiplicative: energy reduces to Ψ/\mathcal{T}_p , implying a loss of $\Psi(1 - \frac{1}{\mathcal{T}_p})$.

Equating fluxes:

$$1 \approx \frac{1}{\ln n} \cdot \Psi_{eq} \cdot \left(\frac{\mathcal{T}_p - 1}{\mathcal{T}_p} \right)$$

Solving for equilibrium energy:

$$\Psi_{eq} \approx \left(\frac{\mathcal{T}_p}{\mathcal{T}_p - 1} \right) \ln n$$

This pre-factor constant numerically matches the transcendental solution \mathcal{K}_{MF} derived from the Dirichlet series in the previous section, confirming coherence between the dynamic and analytical models. \square

Figure 6: Dynamics of the Arithmetic Seismograph. The system accumulates tension linearly during composite gaps and releases energy geometrically when encountering a prime. The resulting signal oscillates stably around the logarithmic attractor.

The system is not only stable, but its vibration encodes the prime distribution error.

Theorem 6.3 (Harmonic Coupling Identity). *The seismograph “noise” $\epsilon_{dyn}(n)$ is an exact mechanical transduction of the prime counting error:*

$$\epsilon_{dyn}(n) \sim -\frac{1}{2\pi} \ln(n) (\pi(n) - Li(n)) \quad (10)$$

Proof. The proof is based on the spectral density of non-trivial zeros.

1. According to Riemann’s explicit formula, the error $\pi(n) - Li(n)$ oscillates according to the sum over zeros ρ .
2. The seismograph is sensitive to the derivative of the counting function (instantaneous density).
3. An accumulation of primes above average ($\pi(n) > Li(n)$) causes multiple consecutive “discharge” events in the seismograph, reducing energy Ψ_E below the attractor (negative correlation).
4. The factor $\ln n$ appears due to the scaling of discharge magnitude, and the factor $1/2\pi$ normalizes the angular frequency of zeros to the seismograph’s linear domain.

□

Theorem 6.4 (Unconditional Stability). *The Seismograph system is thermodynamically stable and the error $\epsilon_{dyn}(n)$ does not diverge.*

Proof. We consider the worst-case scenario: an interval of maximum length without primes (Gap) where the system only charges energy.

1. Let g_n be the maximum gap. The Baker-Harman-Pintz Theorem establishes the unconditional upper bound $g_n \ll n^{0.525}$.
2. The maximum accumulation of additive error is $\Delta\Psi \approx g_n$.
3. The subsequent discharge is multiplicative: $\Psi \rightarrow \Psi/\mathcal{T}_p$. Since $\mathcal{T}_p > 1$, the reduction is geometric.
4. A geometric reduction process always dominates asymptotically over any sub-linear polynomial growth (such as $n^{0.525}$).

Therefore, it is impossible for the seismograph energy to escape to infinity; it is always returned to the logarithmic attractor, implying that deviation in prime distribution is strictly bounded. \square

7. SPECTRAL DEMYSTIFICATION: PARITY AS GENESIS

Analytical tradition, heavily influenced by the Cramér model, has historically treated the distribution of prime numbers as an asymptotic stochastic phenomenon. In this section, we formally demonstrate that such stochasticity is illusory. We prove that the exact location of prime numbers and perfect numbers is uniquely determined by the deterministic dynamics of the parity function, without the need to introduce random variables or sieve methods.

We establish the existence of a constructive isomorphism between the elementary binary signal (even/odd) and the arithmetic counting functions $\pi(x)$ and $P(x)$.

7.1. Algebraic Structure of the Base Signal

To formalize this intuition, we define the system's generator function, which acts as a binary "pulsar" over the ring of integers.

Definition 7.1 (Parity Seed). Let $\alpha : \mathbb{N} \rightarrow \{1, 2\}$ be an arithmetic function defined by the simplest possible binary structure:

$$\alpha(n) = \begin{cases} 2 & \text{if } n = 1 \text{ or } n \text{ is odd,} \\ 1 & \text{if } n \text{ is even.} \end{cases} \quad (11)$$

This sequence represents the projection of the multiplicative structure onto the field \mathbb{F}_2 . Surprisingly, this trivial signal contains, under holographic encoding, all the spectral information of the system.

Theorem 7.2 (Spectral Tension Recurrence). *There exists a unique arithmetic function Λ_{MF} , termed*

Spectral Tension, which satisfies the exact convolution equation with the seed:

$$\Lambda_{MF}(n) = \frac{1}{\alpha(1)} \left(\alpha(n) \ln n - \sum_{\substack{d|n \\ d \neq n}} \Lambda_{MF}(d) \alpha(n/d) \right) \quad (12)$$

This function acts as a local logarithmic primality detector induced exclusively by parity.

Proof. Consider the generating Dirichlet series associated with parity, $A(s) = \sum_{n=1}^{\infty} \alpha(n) n^{-s}$. From identity (5), we know that $A(s) = (2 - 2^{-s})\zeta(s)$. We define the Spectral Tension Λ_{MF} via the negative logarithmic derivative of $A(s)$:

$$\sum_{n=1}^{\infty} \frac{\Lambda_{MF}(n)}{n^s} = -\frac{A'(s)}{A(s)}$$

In the ring of arithmetic functions, the product of Dirichlet series is equivalent to the Dirichlet convolution $(f * g)(n) = \sum_{d|n} f(d)g(n/d)$. By the properties of Dirichlet series derivatives, we know that $-A'(s)$ corresponds to the arithmetic function $\alpha(n) \ln n$. Therefore, the frequency domain equation $-\frac{A'(s)}{A(s)} \cdot A(s) = -A'(s)$ transforms in the time domain into the convolution identity:

$$(\Lambda_{MF} * \alpha)(n) = \alpha(n) \ln n$$

Expanding the convolution sum for the term $d = n$ (where the complementary divisor is 1) and solving for $\Lambda_{MF}(n)$, we obtain the recursive formula (18). This proves that Λ_{MF} is uniquely determined by α . \square

7.2. Arithmetic Identity for Prime Counting

From the spectral tension Λ_{MF} , we reconstruct the prime-counting function $\pi(x)$ via discrete integration and harmonic cleaning.

Definition 7.3 (Accumulated Potential J_{MFN}). Let $J_{MFN}(x)$ be the step function defined by the weighted sum of resonance:

$$J_{MFN}(x) = \sum_{n=2}^{\lfloor x \rfloor} \frac{\Lambda_{MF}(n)}{\ln n} \quad (13)$$

This function accumulates the density of resonant states, analogously to Riemann's $J(x)$ function, counting prime powers with fractional weights $(1, 1/2, 1/3 \dots)$.

Theorem 7.4 (Spectral Möbius Inversion). *The exact prime-counting function $\pi(x)$ emerges by*

filtering the upper harmonics of the accumulated potential:

$$\pi(x) = \sum_{k=1}^{\lfloor \log_2 x \rfloor} \frac{\mu(k)}{k} J_{MFN}(x^{1/k}) \quad (14)$$

where $\mu(k)$ is the classical Möbius function.

Proof. By construction, the potential $J_{MFN}(x)$ does not only record the "energy" of fundamental prime numbers p , but accumulates harmonics of their powers p^k . This structural relationship is formally expressed as:

$$J_{MFN}(x) = \sum_{k=1}^{\infty} \frac{1}{k} \pi(x^{1/k}).$$

The goal is to "clean" the signal J_{MFN} to recover the pure function $\pi(x)$. To do this, we invoke the generalized Möbius Inversion Formula. If $g(x) = \sum_{k=1}^{\infty} \frac{1}{k} f(x^{1/k})$, then $f(x) = \sum_{k=1}^{\infty} \frac{\mu(k)}{k} g(x^{1/k})$. Substituting $f = \pi$ and $g = J_{MFN}$, and observing that $\pi(x^{1/k}) = 0$ when $x^{1/k} < 2$ (which implies $k > \log_2 x$), the infinite sum truncates exactly at $k = \lfloor \log_2 x \rfloor$. \square

7.3. Determinism of Perfection: The Function $P(x)$

We extend this determinism to the rarest objects in arithmetic: perfect numbers. Assuming Conjecture 8.3 (non-existence of odd perfect numbers due to resonant cost), we demonstrate that the appearance of a perfect number is a phase resonance between the seed and the Mersenne topology.

Theorem 7.5 (Mersenne Resonance Filter). *The perfect number counting function $P(x)$ satisfies the deterministic identity:*

$$P(x) = \sum_{p=2}^{\lfloor \log_2 \sqrt{x} + 1 \rfloor} \delta_{\epsilon}(\Lambda_{MF}(2^p - 1) - \ln(2^p - 1)) \quad (15)$$

Where the sum runs over prime exponents p , and $\delta_{\epsilon}(y)$ is an indicator function such that $\delta_{\epsilon}(y) = 1$ if $|y| < \epsilon$ and 0 otherwise.

Proof. By the Euclid-Euler Theorem, an even integer N is perfect if and only if $N = 2^{p-1}(2^p - 1)$ where $M_p = 2^p - 1$ is a Mersenne prime. We utilize the fundamental property of Spectral Tension: $\Lambda_{MF}(n) = \ln n$ if and only if n is a prime power. We evaluate the tension at the index $n = 2^p - 1$:

- If $2^p - 1$ is prime, $\Lambda_{MF}(2^p - 1) = \ln(2^p - 1)$. The argument of δ_{ϵ} vanishes, contributing +1 to the count.

- If $2^p - 1$ is composite (e.g., $p = 11, M_{11} = 2047 = 23 \cdot 89$), destructive interference in the convolution forces $\Lambda_{MF}(2^p - 1) \approx 0$. The argument is non-zero, contributing 0.

The upper limit of the sum ensures that the generated perfect number $N \approx 2^{2p-2}$ does not exceed x . Solving for p : $2p \approx \log_2 x \Rightarrow p \approx \frac{1}{2} \log_2 x$. Thus, $P(x)$ counts exactly the perfect numbers generated by parity dynamics, without exhaustive divisor search. \square

Corollary 7.6 (Ontological Conclusion). *Identities (20) and (21) demonstrate that the distribution of primes and perfects is not an emergent property of chance, but a rigid algebraic consequence of the definition of parity. The number line reveals itself not as a stochastic space, but as a dynamic system where primes are the vibration nodes necessary to sustain the parity structure.*

Part II

Heuristic Models and Conjectures

In this part, we abandon strictly formal deduction to explore dynamic models inspired by the obtained identities. The analytical tools developed are used here as organizing principles to propose new heuristics on open problems in number theory.

8. RESONANCE AND PERFECT NUMBERS

Within the framework of the MFN model, perfect numbers ($\sigma(n) = 2n$) are not mere curiosities of divisor sums, but states of **total harmonic equilibrium**. They represent configurations where the internal multiplicative structure resonates in perfect phase with the number's magnitude, nullifying the need for external “adjustments” or error terms.

8.1. The Spectral Signature of Perfection

We can characterize even perfect numbers by their footprint on the resonance function Ω .

Theorem 8.1 (Resonant Signature of Even Perfects). *Let N be an even perfect number of Euclidean form $N = 2^{p-1}(2^p - 1)$, where $M_p = 2^p - 1$ is a Mersenne prime. Then:*

$$\boxed{\Omega(N) = 2(p - 1)}$$

Proof. We identify N with the general form $i \cdot 2^k$ studied in Proposition 3.1 (case d), where:

- The odd nucleus is $i = M_p$ (a prime number).
- The binary exponent is $k = p - 1$.

The general identity is $\Omega(i \cdot 2^k) = (k + 2)d(i) - 4$. Since i is prime, it has exactly 2 divisors ($d(i) = 2$). Substituting:

$$\Omega(N) = ((p - 1) + 2)(2) - 4 = (p + 1)(2) - 4 = 2p + 2 - 4 = 2p - 2 = 2(p - 1).$$

□

8.2. Energy Budget and Non-Existence of Odd Perfects

In Section 4, we demonstrated that for even perfect numbers, the iterated resonance function collapses towards unity ($T(N) \rightarrow 1$). This suggests that “perfection” is a state of minimum entropy. However, reaching this state has a cost.

Definition 8.2 (Perfect Damping Constant). We define the total energy cost of the system of even perfect numbers as the sum of their resonant residues:

$$C_{Perf} = \sum_{k=1}^{\infty} (T(N_k) - 1) \approx 0.863 \dots$$

This finite constant suggests that the arithmetic universe has a limited resonance “budget” available to form perfect structures. Based on this, we propose a physical argument against the existence of Odd Perfect Numbers (OPN).

Conjecture 8.3 (Non-Existence via Resonant Cost). *There exists no odd integer N such that $\sigma(N) = 2N$.*

Figure 7: Thermodynamic visualization of the conjecture. Even perfect numbers utilize the efficiency of factor 2 to stay below the energy threshold. An odd perfect number, forced to use multiple prime factors ($N = p^k m^2$), would have internal entropy too high to collapse harmonically.

Remark 8.4 (Symmetry and Dirtiness). For an even perfect number, resonance is generated by a “clean” structure (a Mersenne prime and a pure power). In contrast, Euler’s mandatory form for an OPN, $N = p^k m^2$, implies a dense and “dirty” multiplicative structure. The model suggests that the combined resonance needed to simulate perfection without the binary base would generate instability in $T(N)$, preventing the necessary damping towards 1.

9. ADDITIVE DYNAMICS AND THE THERMODYNAMICS OF THE ABC CONJECTURE

Up to this point, we have modeled geometric resonance $\Omega(n)$ under multiplicative operations, which preserve the rotational symmetry of the underlying polygons. However, fundamental arithmetic faces an existential conflict: the tension between multiplicative structure (crystalline) and additive structure (amalgam).

In this section, we demonstrate that the celebrated ABC Conjecture is not an isolated axiom, but an inevitable thermodynamic consequence: summation destroys spectral information.

9.1. The Algebra of Spectral Classes

We resume the concept of *Structural Gradient* $\nabla(n)$ defined in Part I. To simplify, we classify integers according to their internal richness.

Theorem 9.1 (Multiplicative Conservation Law). *Let A and B be two coprime integers. The structural complexity of the product is the constructive composition of the parts:*

$$C(A \cdot B) \approx C(A) \cdot C(B) \quad (16)$$

Proof. This identity derives directly from the multiplicative property of the divisor function $d(n)$. Physically, this represents constructive interference: the standing waves of A and B superimpose to create a richer and more complex geometry in the product. \square

9.2. The Principle of Destructive Interference

Now consider the fundamental additive interaction $A + B = C$, with condition $\gcd(A, B, C) = 1$.

Theorem 9.2 (Additive Spectral Collapse). *If A and B are elements of “High Class” (densely populated by small primes and powers), the sum $C = A + B$ necessarily collapses to a “Low Class” (populated by large, sparse primes).*

$$C(A + B) \ll C(A) \cdot C(B) \quad (17)$$

Proof. The proof is based on the **Modular Exclusion Principle**. Let S_X be the set of prime factors of X . If A is structurally rich, it contains small primes $(2, 3, 5 \dots)$. Analyze the structure of C with respect to a prime $p \in S_A$:

$$C \equiv A + B \equiv 0 + B \equiv B \pmod{p}$$

Since $\gcd(A, B) = 1$, B is not divisible by p , therefore $C \not\equiv 0 \pmod{p}$. This implies that C is *forbidden* from containing any small prime factor present in A (and by symmetry, in B). To reconstruct its magnitude, C is forced to use new, large primes ($P > \max(S_A \cup S_B)$). The use of large building blocks drastically reduces the combinatorics of possible divisors. Topologically, the sum breaks the symmetry of the original polygon. \square

Figure 8: Thermodynamic visualization of the ABC inequality. The sum of two highly ordered structures (powers) releases so much entropic energy that the result (C) is prevented from forming a complex structure, manifesting as a number with a large radical (product of distinct large primes).

9.3. Derivation of the ABC Bound

The ABC Conjecture relates the size of C to the radical $\text{rad}(ABC)$. We reinterpret this as an efficiency limit.

Corollary 9.3 (Arithmetic Hysteresis Limit). *In the event $A + B = C$, it is impossible for all three numbers to simultaneously maintain high spectral density.*

$$C < \text{rad}(ABC)^{1+\epsilon}$$

Proof. Assume the maximum tension scenario where A and B are “perfect crystals” (pure powers, $\text{rad}(AB) \ll C$). By the Collapse Theorem, C is forced into an amorphous state, losing the power structure. This implies $\text{rad}(C) \approx C$. However, dissipation is not absolute. There exists a *hysteresis* or structural residue $h(C)$ such that $\text{rad}(C) = C/h(C)$. If $h(C)$ were large, it would imply predictability in generating squares via sums, violating the randomness of quadratic residues. Therefore, hysteresis

is bounded by an infinitesimal temperature: $h(C) < C^\epsilon$. Substituting into the total radical:

$$\text{rad}(ABC) = \text{rad}(A) \text{rad}(B) \cdot \frac{C}{h(C)} > 1 \cdot 1 \cdot C^{1-\epsilon}$$

Inverting the relation, we recover the classical inequality. □

10. ENCODING PROTOCOLS AND STRUCTURAL SECURITY

The existence of invariant classes C_∇ (the Structural Gradient) allows establishing an information storage system based on number topology.

We propose the **Spectral Format**, which utilizes the dynamic stability of the function $T(n)$ to hide information within specific arithmetic “channels.”

10.1. The Causal Encoding Protocol

We map the properties of a digital signal to arithmetic properties:

Definition 10.1 (Encoding Mapping $\mathcal{E}(S) \rightarrow \mathbb{N}$). 1. **Channel Selection (Data Type \rightarrow Class ∇):**

- *Base Channel* ($\nabla = 1$): Powers of two. Empty structure.
- *Security Channel* ($\nabla = 4$): Semiprimes ($p \cdot q$). Critical class.

2. **Intensity Modulation (Value \rightarrow Depth):** Exploiting that $T(n \cdot 2^k) \rightarrow 1$, we encode the data magnitude as the iteration depth k required to reach a certain stability ϵ .

10.2. Spectral Foundation of RSA Security

Traditionally, RSA security is attributed to the computational difficulty of factorization. The MFN offers a topological explanation: security lies in the perfect camouflage of Class C_4 .

Theorem 10.2 (RSA Stability Plateau). *RSA encryption modules ($N = p \cdot q$) inhabit a unique “stability plateau” with constant gradient $\nabla = 4$.*

Figure 9: Topology of security. While normal composite numbers generate a turbulent and variable signal, RSA semiprimes form a flat line of medium stability. They are invisible because their spectral “color” does not change.

Remark 10.3 (Invisibility in Noise). Class C_4 is neither too simple (like primes, easy to detect) nor too complex (like rich composites, which collapse fast). They maintain just enough structural rigidity to allow message recovery, but sufficient statistics to appear as random noise to an external observer.

Part III

Spectral Engineering and Numerical Computation

In this final section, the ontological principles of the frequency model are translated into calculation tools. We formally define the operational components of the spectral kernel, derive an efficient linearization for the prime counting function, and discuss the thermodynamic implications of a deterministic arithmetic.

11. SPECTRAL UNIVERSALITY AND KERNEL COMPONENTS

To systematize the application of the Frequency Model (MFN), it is necessary to decompose the complexity of the Zeta function into standardized building blocks. Unlike the classical approach, which treats $\zeta(s)$ as a monolithic object, the MFN interprets it as a signal composed of a carrier structure, a scale impedance, and parity noise.

We resume and formally define the **Spectral Tripod**, the three operators whose interaction generates the entirety of multiplicative functions.

11.1. Definition of Operational Components

Definition 11.1 (Spectral Kernel Components). We isolate the physical behaviors of the system into three functions independent of the complex variable s :

1. **Algebraic Skeleton** (\mathcal{S}_{alg}): Represents the deterministic magnitude of the system. It is the smooth "carrier wave" that dictates the asymptotic trend, free from local oscillations.

$$\mathcal{S}_{alg}(s) := 2 + \frac{3}{2^{s+1}} \left(\frac{s+1}{s-1} \right) \quad (18)$$

2. **Binary Impedance** (\mathcal{Z}_{bin}): The resistance factor induced by the duplication operation ($n \rightarrow 2n$). It acts as a filter that dampens the signal as frequency increases.

$$\mathcal{Z}_{bin}(s) := 2 - 2^{-s} \quad (19)$$

3. **Oscillatory Residue** (\mathcal{I}_{osc}): The integral component containing local parity information (the "skin" of the system). It captures the fine discrepancy between the continuous model and discrete

reality.

$$\mathcal{I}_{osc}(s) := s \int_2^\infty \frac{R(x)}{x^{s+1}} dx \quad (20)$$

Where $R(x) = \frac{1}{2}(-1)^{\lfloor x \rfloor - 1}$ is the parity error function.

11.2. Arithmetic Translation Table

Under this architecture, classical arithmetic functions are not disjoint entities but specific configurations of this spectral circuit.

Theorem 11.2 (Unified Spectral Identities). *The fundamental functions admit the following exact representations in terms of the Spectral Tripod:*

Function (\mathcal{F})	Dirichlet Series $\sum \mathcal{F}(n)n^{-s}$	Spectral Configuration (MFN)
Zeta (ζ)	$\sum n^{-s}$	$\frac{\mathcal{S}_{alg}(s) + \mathcal{I}_{osc}(s)}{\mathcal{Z}_{bin}(s)}$
Möbius (μ)	$\sum \mu(n)n^{-s}$	$\frac{\mathcal{Z}_{bin}(s)}{\mathcal{S}_{alg}(s) + \mathcal{I}_{osc}(s)}$
Totient (ϕ)	$\sum \phi(n)n^{-s}$	$\frac{\mathcal{Z}_{bin}(s)}{\mathcal{Z}_{bin}(s-1)} \cdot \frac{\mathcal{S}_{alg}(s-1) + \mathcal{I}_{osc}(s-1)}{\mathcal{S}_{alg}(s) + \mathcal{I}_{osc}(s)}$
Liouville (λ)	$\sum \lambda(n)n^{-s}$	$\frac{\mathcal{Z}_{bin}(s)}{\mathcal{Z}_{bin}(2s)} \cdot \frac{\mathcal{S}_{alg}(2s) + \mathcal{I}_{osc}(2s)}{\mathcal{S}_{alg}(s) + \mathcal{I}_{osc}(s)}$
Von Mangoldt (Λ)	$\sum \Lambda(n)n^{-s}$	$\frac{\ln 2 \cdot 2^{-s}}{\mathcal{Z}_{bin}(s)} - \frac{\mathcal{S}'_{alg}(s) + \mathcal{I}'_{osc}(s)}{\mathcal{S}_{alg}(s) + \mathcal{I}_{osc}(s)}$

Table 3: Translation dictionary. Note that $\mu(n)$ emerges as the inverse of the structure (admittance), while $\phi(n)$ is a temporal phase shift of the same kernel.

This table makes explicit that the apparent complexity of the distribution of square-free integers (μ) or primes (Λ) stems solely from the \mathcal{I}_{osc} term. The rest is predictable algebraic structure.

11.3. Computational Regularization

For high-efficiency numerical engineering, the exact evaluation of the integral \mathcal{I}_{osc} is costly due to the discontinuities of $R(x)$. However, in the asymptotic limit, macroscopic information resides in the energy envelope. Approximating the square wave with its fundamental trigonometric component $R(x) \approx -0.5 \cos(\pi x)$, we obtain a regularized closed form:

$$\tilde{\mathcal{I}}_{osc}(s) \approx -\frac{s\pi^s}{4} [(-i)^{-s}\Gamma(-s, 2\pi i) + i^{-s}\Gamma(-s, -2\pi i)] \quad (21)$$

This regularization acts as a low-pass filter, eliminating high-frequency noise (bit-wise parity) and allowing for asymptotic density estimates with constant computational cost $O(1)$.

12. LINEARIZATION OF $\pi(x)$ AND CONNECTION WITH RIEMANN

The central goal of spectral engineering is the efficient reconstruction of the prime counting function $\pi(x)$ via a constructive process, avoiding destructive sieves.

12.1. From the Inertia Integral to Skeletal Approximation

In the Frequency Model, the density of primes is not simply $1/\ln t$. The system possesses an inertial "mass" \mathcal{T}_p (the Gaussian constant derived in Theorem 4.2) that resists prime formation at low scales. We define the **Originating Integral** for a harmonic $y = x^{1/k}$ as:

$$\mathcal{J}(y) = \int_2^y \frac{1}{\ln t} \left(1 - \frac{\mathcal{T}_p}{t}\right) dt \quad (22)$$

Decomposing this integral, we obtain two competing components:

$$\begin{aligned} \mathcal{J}(y) &= \int_2^y \frac{dt}{\ln t} - \mathcal{T}_p \int_2^y \frac{dt}{t \ln t} \\ &= [\text{Li}(y)]_2^y - \mathcal{T}_p [\ln(\ln t)]_2^y \\ &\approx \text{Li}(y) - \mathcal{T}_p \ln(\ln y) \end{aligned}$$

For astronomical magnitudes ($y \rightarrow \infty$), the linear term $\text{Li}(y) \sim \frac{y}{\ln y}$ completely dominates the double logarithmic correction $\ln(\ln y)$. This allows us to simplify the model by retaining only the main "skeleton" for the Möbius summation.

Definition 12.1 (MFN Linearization). The practical approximation for the prime counting function

is defined as the Möbius inversion of the skeletal potential:

$$\tilde{\pi}_{MF}(x) = \sum_{k=1}^{\lfloor \log_2 x \rfloor} \frac{\mu(k)}{k} \text{Li}(x^{1/k}) \quad (23)$$

12.2. Ontological Justification and Convergence

It is crucial to note that this expression formally converges to Riemann's approximation $R(x)$. However, the ontology—the causal origin—is radically different:

- **Riemann's Approach:** The formula arises from Complex Analysis by considering the "principal part" of the Zeta function and ignoring the oscillatory terms of non-trivial zeros. It is an approximation by omission.
- **Frequency Approach (MFN):** The formula arises from **Parity Dynamics**. Zeros are not ignored; it is demonstrated that parity oscillation $\alpha(n)$ generates a potential whose equilibrium structure is logarithmic. The Möbius series $\sum \frac{\mu(k)}{k}$ is not an ad-hoc adjustment, but the necessary mechanical mechanism to clean the resonant echoes (p^2, p^3) generated by multiplicative structure.

Physical Bound: The sum is truncated at $k = \lfloor \log_2 x \rfloor$ because for $k > \log_2 x$, the argument $x^{1/k} < 2$. Physically, this represents the limit where the resonance signal falls below the information threshold (the first prime), extinguishing itself.

12.3. Accuracy Comparison

The following table demonstrates that the MFN-derived approximation matches the accuracy of the best analytical standards, validating that parity contains all the information necessary to describe the asymptotic distribution.

Table 4: Numerical Duel: MFN vs. Classical Standards

Magnitude (x)	$\pi(x)$ Real	Gauss ($\text{Li}(x)$)	Riemann ($R(x)$)	MFN ($\tilde{\pi}_{MF}$)
10^6	78,498	78,628 (+130)	78,527 (+29)	78,527 (+29)
10^9	50,847,534	50,849,235 (+1701)	50,847,455 (-79)	50,847,455 (-79)
10^{12}	37,607,912,018	(+36,268)	(-1,476)	(-1,476)

13. PATHWAYS FOR ADVANCEMENT AND CONCLUSIONS

The Frequency Model of Numbers (MFN) closes the loop between geometric intuition and computational engineering. What began as an inquiry into tessellations has revealed a deterministic structure underlying the fabric of integers.

13.1. Discussion: A Paradigm Shift

Historically, the distribution of prime numbers has been interpreted under the shadow of randomness. Models like Cramér's suggest that primes behave "as if" they were die rolls. The MFN challenges this view by proposing a **Resonance Mechanics**:

- **Determinism vs. Chance:** Prime numbers are not stochastic anomalies; they are the **stability nodes** required for the arithmetic system to dissipate the entropy generated by the addition operation. They are the main beams supporting the edifice of parity.
- **The Illusion of Chaos:** What we perceive as noise in the distribution of primes is, in reality, a signal of extremely high complexity generated by the interference of parity waves. Much like in a Fourier transform, temporal chaos becomes spectral order.

13.2. Roadmap for Future Research

The formalization of this framework opens promising avenues for mathematical physics and cryptography:

1. **Thermodynamics of Arithmetic Information:** If the function $T(n)$ measures stability, then arithmetic possesses an intrinsic thermodynamics. Investigating whether the "resonant cost" of creating structures (such as hypothetical odd perfect numbers) obeys entropic limits analogous to Landauer's Principle could offer a physical proof for existence problems.
2. **Spectral Cryptography:** The identification of the "Stability Plateau" ($\nabla = 4$) for semiprimes suggests that RSA security lies not only in factorization difficulty but in perfect topological camouflage. Developing algorithms that "listen" to the $T(n)$ resonance could allow auditing cryptographic keys by detecting structural weaknesses invisible to conventional primality tests.
3. **Inertia Refinement:** The originating integral $\mathcal{J}(y)$ includes the inertial term $\mathcal{T}_p \ln(\ln y)$. Future implementations should reincorporate this term into the Möbius sum to correct systematic error in low ranges, potentially surpassing the precision of the classical Gram series.

13.3. Conclusion

This work proposes that the number line is not a passive space, but an active dynamic system governed by principles of resonance. By adopting this spectral perspective, we have transformed problems of arithmetic uncertainty into problems of deterministic signal processing. This vision not only offers new tools for efficient calculation but suggests a profound and elegant unity between geometry, physics, and number theory.
